

## Notes on Eaton and Kortum 2002, by Mike Waugh

Eaton and Kortum (2002) is easily one of the more important papers written in the last (looks at calendar) 25 years. There are *multiple* facets of this paper that make a contribution, but let me focus on a trade issue: Reviving the Ricardian model and focus on technology as a determinant of trade flows. Recall, leading into 2000s essentially trade was motivated by variety (either Armington or monopolistic competition models), i.e. “fruit salad” models. The concept of trade driven by comparative advantage was dead (more or less).

The big issue with the Ricardian model was that it was hard to connect with the “real world” in any substantive way. For example, Leamer and Levinsohn (1995) said “It’s just too simple.” At this point there was a very important contribution to the Ricardian model which was the Dornbusch et al. (1977) model with two countries and a continuum of goods. How’d they solve it? DFS used a natural ordering between the two countries,  $A(z)$  schedule, which says:

$$A(z') > A(z) \quad \text{if} \quad z' < z \tag{1}$$

meaning the home country has a greater comparative advantage in the good  $z'$  than  $z$ . How to do this for many countries? I could bilaterally order them, but that would be silent regarding the third option of the country left out. Wilson (1980) tried to work this out and it did not go far. The bottom line was that leading into the 2000s Ricardian ideas were not treated as empirically relevant.

Eaton and Kortum (2002) was a paradigm shift with multiple innovations. I’ll talk through a couple that are relevant (focused on trade) for these notes.<sup>1</sup>

First, was how to handle the “ordering problem.” Their idea was to treat the productivity for each individual good as random variables. Then track aggregate trade flows as the probability that a country is a low-cost supplier or not. Note that this is a conceptually important point that should be thought of as separate from the next contribution.

A second contribution: make very particular assumptions on the distributions which result in/ preserve a lot of intuition from DFS and the old (two by two) Ricardian model AND provide a tight mapping of aggregate trade flows to primitives through a gravity equation. Basically, trade flows boil down to four things:

1. **TFP** — There is be a technology term ( $T_s$ ) which is like TFP in a sense. Countries with better technology trade less, but other countries want to buy more from them.

---

<sup>1</sup>Two other literatures that it had a big impact on. One is are labor market models of selection (aka Roy (1951) models) with Lagakos and Waugh (2013), Young (2013), and Hsieh, Hurst, Jones, and Klenow (2019) being examples. The other is the quantitative spatial models as in Ahlfeldt, Redding, Sturm, and Wolf (2015) and Redding and Rossi-Hansberg (2017) is the canonical treatment.

2. **Trade Frictions** — They play the same role as in DFS by generating sets of non-traded goods and reduce overall flows on the intensive and extensive margin.
3. **Factor Costs** — This is the key equilibrium object. A country may have high TFP but also high wages. This is a force that allows other countries a chance to trade.
4. **A notion of comparative advantage** — How much technology, trade frictions, factor costs impede or facilitate trade depends upon the motives for trade. In the EK this boils down to a parameter  $\theta$  which controls how different, at an idiosyncratic level, countries are. This is a second force that allows countries to trade. For example, identical countries at the aggregate level, are different at an idiosyncratic level and hence there is a motive for trade. Interestingly, this parameter turns out to play the exact same role as in the Armington model, i.e. how much I care about a “fruit salad.”

One more thing which I won’t go into detail in these notes is the micro-foundations for the distributional assumptions that they make. Their choices were not random, nor purely for convenience. They relate to earlier work by Jonathan and Sam and specifically Sam’s job market paper. So if someone just looked at the Eaton and Kortum (2002) randomly, it would seem odd or as some people say “Fréchet magic.” Yes, the way things work out is magical. However, to them, the Fréchet assumption was built upon a deliberate thought process over a decade that this was *the* way to think about technology.

## 1. The EK Environment

This section outlines the physical environment of the EK model. I keep it brief since most aspects are known and highlight certain generalizations that I entertain.

**Commodity space:** Goods are indexed by  $\omega \in [0, 1]$ . There are  $J$  countries. Competitive producers in each country can produce good  $\omega$ , so each country’s “version” of  $\omega$  is not differentiated — they are perfect substitutes.

**Technologies and Trade frictions.** Competitive producers in country  $i$ , to produce a good  $\omega$ , have access to a labor only technology defined by the productivity level  $z_i(\omega)$ . Specifically, all producers of good  $\omega$  in country  $i$  have access to the production function:

$$c_i(\omega) = z_i(\omega)n_i(\omega), \quad (2)$$

where labor,  $n_i(\omega)$ , is the only factor of production.

Frictions to trade are modeled as iceberg trade costs. I are using the EK notation where the first subscript is the importer, the second sub-script is the exporter. So for a producer to supply

good  $\omega$  in market  $n$ , from  $i$ , they face an iceberg cost to trade:

$$d_{ni} \geq 1, \quad d_{ii} = 1 \quad (3)$$

and a triangle inequality is assumed to hold (so that I only need to consider direct routes). When the iceberg assumption is combined with the production structure in (2), this means that producers in country  $i$  use different technologies to supply their good to each destination. Put another way, the production function to produce in  $i$  to supply some quantity to country  $n$  of good  $\omega$  is

$$c_{ni}(\omega) = d_{ni}^{-1} z_i(\omega) n_{ni}(\omega). \quad (4)$$

where now  $n_{ni}(\omega)$  is the labor used in the production for delivering goods from  $i$  to  $n$ .

A key idea in the EK model is that good-level technology is characterized in aggregate by a probability distribution. So that a producer of any good in country  $i$  receives a draw from a country-specific distribution with CDF  $F_i(z_i)$ . For now, I simply assume that this distribution is continuous with full support on  $(0, \infty)$ . I will revisit the specific Fréchet distributional assumption that EK make later.

**Consumers.** In each country, there is a representative consumer with preferences:

$$U_n = \int_0^1 \left\{ \sum_j x_{nj}(\omega) u(c_{nj}(\omega)) \right\} d\omega. \quad (5)$$

where  $x_{nj}(\omega)$  is an indicator function that takes the value one if good  $\omega$  is sourced from  $j$  and zero for all other destinations. I express preferences in this way to emphasize the discrete choice nature of the problem. The representative consumer views the good  $\omega$  from different destinations as perfect substitutes, so one unit of  $c_{nj}(\omega)$  delivers the same number of utils as  $c_{nj'}(\omega)$  and thus sources the good from only one destination.

The other deviation from the standard presentation of the EK environment is I do not immediately impose CES preferences. Instead, I start with a general additively separable structure and simply assume that  $u$  is differentiable and strictly concave.

**Endowments.** Finally, each country has a labor endowment of mass of  $N_i$  and the representative consumer in each country supplies his labor inelastically.

This completes the description of the physical environment.

## 1.1. The Consumers Problem

The representative consumer in country  $n$  faces the problem:

$$U_n = \max_{\{n_{in}(\omega), x_{nj}(\omega), c_{nj}(\omega)\}} \int_0^1 \left\{ \sum_j x_{nj}(\omega) u(c_{nj}(\omega)) \right\} d\omega \quad (6)$$

subject to two constraints:

$$\int_0^1 \sum_{i \in J} \left\{ w_{in}(\omega) n_{in}(\omega) \right\} d\omega \geq \int_0^1 \left\{ \sum_j x_{nj}(\omega) p_{nj}(\omega) c_{nj}(\omega) \right\} d\omega \quad [\lambda_n], \quad (7)$$

$$N_n \geq \int_0^1 \sum_{i \in J} n_{in}(\omega) d\omega \quad [v_n]. \quad (8)$$

The household chooses where to supply labor  $n_{in}(\omega)$ , where to buy goods from given by the indicator function  $x_{nj}(\omega)$ , and then how much of the good to buy  $c_{nj}(\omega)$ . The two constraints that the household faces are the constraint that the value of goods demanded must be less than labor income and then that labor supply can not be larger than the endowment. Associated with these constraints are the two multipliers  $\lambda_n$  and  $v_n$ . Pedagogical, I entertain the idea that labor markets could have different wages  $w_{in}(\omega)$  depending upon  $\omega$  and destination  $i$ , but as I show below the consumers labor supply choice results in the requirement that wages are equalized across all labor markets.

To solve this problem, there are two standard conditions and a new one regarding the sourcing choice. First, the two standard conditions. The optimal quantity choice satisfies

$$u'(c_{nj}(\omega)) = \lambda_n p_{nj}(\omega), \quad (9)$$

where the marginal utility of the goods is set equal to the marginal cost which is how much income it takes as given by  $p_{nj}(\omega)$  and then converted into utils at the marginal utility of wealth which is given by the multiplier  $\lambda_n$ . And note that I cancelled out the  $x_{nj}(\omega)$  terms that would be on both side of this equation, thus this condition holds (i) if country  $j$  actually is the supplier and (ii) trivially if  $j'$  is not the supplier as both sides are zero.

The labor supply choice satisfies

$$\lambda_n w_{in}(\omega) = v_n, \quad (10)$$

which has the interpretation that the value of supplying labor to any sector, measured in utils which is the wage times the marginal utility of wealth, must equal the shadow value of relaxing

the labor endowment constraint. Since the consumer can freely allocate labor across sectors, this condition must hold for all  $\omega$  and  $i$  destination labor markets. An immediate implication is that wages across different markets are equalized and then the one wage per country is  $w_n$ .

The non-standard condition is the sourcing choice. I characterize the sourcing choice or the  $x_{nj}(\omega)$ s by making good by good comparisons of the Lagrangian as in out Mongey and Waugh (2024) paper. I do this by comparing, for each  $\omega$ , which source  $j$  yields the highest contribution to the Lagrangian:

$$\left[ u(c_{n1}(\omega)) - \lambda_n p_{n1}(\omega) c_{n1}(\omega) \right] \quad \text{vs.} \quad \left[ u(c_{n2}(\omega)) - \lambda_n p_{n2}(\omega) c_{n2}(\omega) \right] \quad \text{vs.} \quad \dots \text{for all } j. \quad (11)$$

This is a comparison across sources which must factor in two distinct issues: (i) how many utils a good from  $j$  versus  $j'$  delivers, **and** (ii) the negative effect of that choice on the budget constraint which is the  $\lambda_n p_{n1}(\omega) c_{n1}(\omega)$ . This comparison leads to the following sourcing choice rule

$$x_{nj}(\omega) = \begin{cases} 1, & \text{if } u(c_{nj}(\omega)) - \lambda_n p_{nj}(\omega) c_{nj}(\omega) \geq \max_{j'} \left\{ u(c_{nj'}(\omega)) - \lambda_n p_{nj'}(\omega) c_{nj'}(\omega) \right\} \\ 0, & \text{otherwise} \end{cases} \quad (12)$$

At this point, this sourcing strategy does not look like the one in Eaton and Kortum (2002). But one can make the argument that it is in the following way. Define the surplus function:

$$S(p_{nj}(\omega)) \equiv u(c_{nj}(\omega)) - \lambda_n p_{nj}(\omega) c_{nj}(\omega), \quad (13)$$

where  $c$  is chosen optimally given  $p_{nj}(\omega)$  in (9) and thus  $S$  is an implicit function of  $p_{nj}(\omega)$ . Written in this form, the source which delivers the highest surplus determines the sourcing strategy. Then differentiate  $S$  with respect to  $p_{nj}(\omega)$ :

$$\frac{dS}{dp_{nj}(\omega)} = \underbrace{[u'(c_{nj}(\omega)) - \lambda_n p_{nj}(\omega)]}_{= \text{zero at optimum}} \frac{dc_{nj}(\omega)}{dp_{nj}(\omega)} - c_{nj}(\omega) \quad (14)$$

$$= -c_{nj}(\omega) < 0 \quad (15)$$

Where the final step follows from noting that the bracketed part is the zero at the optimum. Essentially, this is an application of the envelope theorem. At the optimum, the indirect effect of the price on surplus through the induced change in  $c$  vanishes. Thus, only the direct effect remains, which is  $-c$ .

The implication of the result in (14) is that because  $S$  is strictly decreasing, the comparison of

$$S(p_{nj}(\omega)) \geq S(p_{nj'}(\omega)) \quad (16)$$

holds if and only if  $p_{nj}(\omega) \leq p_{nj'}(\omega)$ . Therefore, the sourcing rule reduces to choosing the source with the lowest price

$$x_{nj}(\omega) = \begin{cases} 1, & \text{if } p_{nj}(\omega) \leq \min_{j'} \left\{ p_{nj'}(\omega) \right\} \\ 0, & \text{otherwise.} \end{cases} \quad (17)$$

Interestingly, in Eaton and Kortum (2002) equation (17) is essentially described as a technology, not an outcome of an optimization problem. Alvarez and Lucas Jr (2007) is another canonical presentation and they give little discussion as to how and when this is the correct strategy. Wilson (1980) starts here too.

I wrote out the problem this way which is very general, but returns us to the basic EK structure. There are a couple of departures from the basic environment that my presentation allows one to think about.

- **Source-specific utility**  $u_j(c)$ . If the utility function depends on the source  $j$ —for example, due to home bias—then the surplus functions  $S_j(\Lambda)$  differ across sources. The sourcing rule no longer reduces to comparing prices alone. Adjustments then would need to be made and the adjustment depends on the preference parameters. How would this work? This is a good place to test out your understanding of the model.
- **Source-variety-specific utility**  $u_{\omega j}(c)$ . This would be something like the quality for each  $\omega$  and source varies. Then sourcing rule requires comparing  $(\omega, j)$ -specific surplus functions, and prices alone are not sufficient either. This case is interesting too because then one could think about a distribution of quality (like technology) and work things out.
- **Customer Heterogeneity.** This is the space that Mongey and I have explored a lot in Mongey and Waugh (2024), Mongey and Waugh (2025), and in my work Waugh (2023). There we have preference shocks, now the  $c$ 's and  $\lambda$ s are moving around depending upon the persons wealth. In these settings, which good is the low price is not sufficient and how consumers select different goods depends upon their level of wealth. The power of structuring the choice of the good this way is that it makes clear how to select the optimal choice when there are complicating features of the model.

## 1.2. The Firms Problem

Competitive producers in  $i$ , supplying  $n$  of good  $\omega$ , simply chose labor to maximize profits. Perfect competition erodes those profits and the he solution that the prices for each good are

$$p_{ni}(z) = \frac{w_i d_{ni}}{z_i(\omega)}. \quad (18)$$

where I have inserted the condition that the wage rate is independent of  $\omega$  or destination of the product  $n$  from the argument above. This is the price consumers in country  $n$  face.

## 2. Aggregation: CES and Fréchet

### 2.1. CES Preferences

Assume the utility function takes the power form:

$$u(c) = c^{\frac{\sigma-1}{\sigma}} \quad (19)$$

Together with the utility specification in (5), this gives a CES utility function. I dispense with the outer power term, but this is without loss since it is simply a monotonic transformation.

With CES utility, the optimal quantity satisfies:

$$\frac{\sigma-1}{\sigma} c_{nj}(\omega)^{-\frac{1}{\sigma}} = \lambda_n p_{nj}(\omega) \quad (20)$$

which gives demand:

$$c_{nj}(\omega) = \left( \frac{\sigma-1}{\sigma} \right)^\sigma \left( \frac{1}{\lambda_n p_{nj}(\omega)} \right)^\sigma \quad (21)$$

The expenditure on good  $\omega$  sourced from  $j$  is:

$$p_{nj}(\omega) c_{nj}(\omega) \propto p_{nj}(\omega)^{1-\sigma} \quad (22)$$

Total expenditure in country  $n$  is:

$$E_n = \int_0^1 \sum_j x_{nj}(\omega) p_{nj}(\omega) c_{nj}(\omega) d\omega \propto \int_0^1 \sum_j x_{nj}(\omega) p_{nj}(\omega)^{1-\sigma} d\omega \quad (23)$$

The expenditure share on goods from country  $j$  is:

$$\frac{\int_0^1 x_{nj}(\omega) p_{nj}(\omega)^{1-\sigma} d\omega}{\int_0^1 \sum_k x_{nk}(\omega) p_{nk}(\omega)^{1-\sigma} d\omega} \quad (24)$$

There are two challenges to evaluating this expression. First, the integral in the numerator is conditioned on  $j$  being the lowest-cost supplier in country  $n$  — that is, on  $x_{nj}(\omega) = 1$ . This leaves open what is the distribution of prices that actually show up in a given country from a given destination. Second, the denominator involves the distribution of all prices actually consumed in country  $n$ . What is that distribution? The Fréchet distribution provides the structure needed to make progress on both.

## 2.2. The Fréchet Distribution

Assume that good-level productivity is drawn from a probability distribution. Specifically, for each good  $\omega$ , productivity  $z_j(\omega)$  in country  $j$  is an independent draw from a Fréchet (Type II extreme value) distribution with CDF:

$$F_j(z) = \exp \{-T_j z^{-\theta}\} = \text{Prob} \{z_j(\omega) \leq z\} \quad (25)$$

where the support is the positive real line, and draws are independent across countries.

This distribution has two parameters which are important to keep in mind:

- The  $T$ s are the centering parameters and these control the mean of the distribution with high  $T$ s meaning that larger  $z$ s are more likely. This is the sense that it determines a country's TFP or how advanced its technology is. But note, since this is a distribution with full support on the positive real line, it will have some bad draws and very good ones too.
- Then there is the  $\theta$  which controls the dispersion of the draws. So the way this is setup is if  $\theta$  is **large**, there is little dispersion (not many bad nor good draws). If  $\theta$  is **small**, then there is a lot of dispersion (many bad and many good draws). In this setting, there is a restriction on the size of  $\theta$ , it can't be below one and it also must be bounded below by  $\sigma$  so that the utility is well defined. This is a detail to see in the paper.

As a preview, the thing that determines things like gains from trade, how much trade responds to changes in trade costs, etc. are fundamentally tied to  $\theta$ . There is tons of intuition about this in the sense that if countries are very different (low  $\theta$ ), then there is more scope for us to be trading as there are more instances where one country is good, another is bad at producing a particular good. Thus, gains from trade will be large. Intuitively, think to yourself how this would work

with high  $\theta$  (we are very similar).

Other details: Micro foundation, max stability, correlation. Fill this in or ask me later.

### 2.3. Next steps...

Given the parameterized distribution, we need figure out how to compute the integrals in the import demand equation. I'm going to do this in several steps:

1. Characterize the distribution of prices in a country.
2. Characterize the distribution of prices **conditional** on being a low cost supplier.
3. Characterize the import share.

### 2.4. Characterizing the Distribution of Prices

We now derive the distribution of prices that consumers actually face in destination  $n$ . For a given good  $\omega$ , we know:

$$\text{Prob} \{z_j(\omega) \leq z\} = \exp \{-T_j z^{-\theta}\} \quad (26)$$

From marginal cost pricing, the price offered by source  $j$  to destination  $n$  is:

$$p_{nj}(\omega) = \frac{w_j d_{nj}}{z_j(\omega)} \iff z_j(\omega) = \frac{w_j d_{nj}}{p_{nj}(\omega)} \quad (27)$$

Substituting:

$$\text{Prob} \left\{ \frac{w_j d_{nj}}{p_{nj}(\omega)} \leq \frac{w_j d_{nj}}{p} \right\} = \exp \{-T_j (w_j d_{nj})^{-\theta} p^\theta\} \quad (28)$$

Since higher  $z_j(\omega)$  means lower  $p_{nj}(\omega)$ , this gives:

$$\text{Prob} \{p_{nj}(\omega) > p\} = \exp \{-T_j (w_j d_{nj})^{-\theta} p^\theta\} \quad (29)$$

And thus the CDF of prices offered by source  $j$ :

$$\text{Prob} \{p_{nj}(\omega) \leq p\} = 1 - \exp \{-T_j (w_j d_{nj})^{-\theta} p^\theta\} \quad (30)$$

The above characterizes prices that **might** be offered to country  $n$  from source  $j$ . But consumers

purchase from the lowest-cost source. The price actually paid for good  $\omega$  is:

$$p_n(\omega) = \min_j \{p_{nj}(\omega)\} \quad (31)$$

which comes from (17). So what we want to compute the distribution of  $p_n(\omega)$ .

**Claim 1:** Flipping the inequality to make the algebra work:

$$\text{Prob} \{p_n(\omega) > p\} = \text{Prob} \{p_{n1}(\omega) > p, p_{n2}(\omega) > p, \dots, p_{nJ}(\omega) > p\} \quad (32)$$

This follows from the fact that if the minimum exceeds  $p$ , then all prices must exceed  $p$ .

**Claim 2:** By independence of productivity draws across countries:

$$\text{Prob} \{p_{n1}(\omega) > p, \dots, p_{nJ}(\omega) > p\} = \prod_{j=1}^J \text{Prob} \{p_{nj}(\omega) > p\} \quad (33)$$

Substituting the survival function for each source:

$$\text{Prob} \{p_n(\omega) > p\} = \prod_{j=1}^J \exp \left\{ -T_j (w_j d_{nj})^{-\theta} p^\theta \right\} \quad (34)$$

$$= \exp \left\{ - \sum_{j=1}^J T_j (w_j d_{nj})^{-\theta} p^\theta \right\} \quad (35)$$

Define:

$$\Phi_n = \sum_j T_j (w_j d_{nj})^{-\theta} \quad (36)$$

Then:

$$\text{Prob} \{p_n(\omega) > p\} = \exp \left\{ -\Phi_n p^\theta \right\} \quad (37)$$

And the CDF of prices actually paid:

$$\text{Prob} \{p_n(\omega) \leq p\} = 1 - \exp \left\{ -\Phi_n p^\theta \right\} \quad (38)$$

This is a Weibull distribution with scale parameter  $\Phi_n^{-1/\theta}$  and shape parameter  $\theta$ . The transformation from productivity (Fréchet, with mass toward large values) to prices (Weibull, with mass toward small values) reflects the inverse relationship between productivity and cost.

Now the  $\Phi$  object is a **key** object. In this model, all that matters for trade is how it shapes the prices that a consumer faces.  $\Phi$  is a summary statistic for this with a lower  $\Phi$  meaning there are the consumer is getting lower prices. With that then notice how this works:

- Summarizes how technology and factor costs *diffuse* through trade.
- Barriers to trade affect prices and “weight” this diffusion.
- Note: if  $d_{ni} = 1$  for all pairs, this implies all countries face the same price distribution, satisfying the **law of one price**.
- An opposite limit is if the country is in autarky. Then only that countries  $T$  matters, there is no benefit of being able to import goods from countries produced using their technology.

One more note. This is actually looking a lot like the inside term of the CES, ideal price index. It turns out that they are related. Can you figure that out?

## 2.5. Computing the Probability that a Country is the Low-Cost Supplier

We now compute the probability that country  $j$  is the low-cost supplier to destination  $n$ . This is the probability that  $x_{nj}(\omega) = 1$ . Country  $n$  buys from source  $j$  if:

$$p_{nj}(\omega) = \min_k \{p_{nk}(\omega)\} = \min_k \left\{ \frac{w_k d_{nk}}{z_k(\omega)} \right\} \quad (39)$$

Equivalently,  $j$  wins if it has the highest cost-adjusted productivity:

$$\frac{z_j(\omega)}{w_j d_{nj}} = \max_k \left\{ \frac{z_k(\omega)}{w_k d_{nk}} \right\} \quad (40)$$

For simplicity, consider two countries and compute the probability that country 2 is the low-cost supplier to country 1. This requires:

$$\frac{z_2(\omega)}{w_2 d_{12}} \geq \frac{z_1(\omega)}{w_1 d_{11}} \quad (41)$$

Rearranging:

$$z_1(\omega) \leq z_2(\omega) \frac{w_1 d_{11}}{w_2 d_{12}} \quad (42)$$

Define  $\tilde{w} = \frac{w_1 d_{11}}{w_2 d_{12}}$  to simplify notation. We want:

$$\text{Prob}\{z_1(\omega) \leq z_2(\omega)\tilde{w}\} = \int_0^\infty \text{Prob}\{z_1(\omega) \leq z_2\tilde{w}\} f_2(z_2) dz_2 \quad (43)$$

This last equation is important to understand and interpret about what is going on. The first term inside the integral is the CDF of country 1's productivity distribution evaluated at the random variable  $z_2\tilde{w}$ . So this is saying, given  $z_2$ , what is the total probability that  $z_1$  is lower. But,  $z_2$  is also a random variable, we add these probabilities over all possible outcomes of  $z_2$  weighted by probability  $z_2$  occurs, i.e. the pdf  $f_2(z_2)$ .

Now substituting the Fréchet CDF and pdf:

$$= \int_0^\infty \exp\{-T_1(z_2\tilde{w})^{-\theta}\} \cdot T_2\theta z_2^{-\theta-1} \exp\{-T_2 z_2^{-\theta}\} dz_2 \quad (44)$$

At this point, one can see where the common  $\theta$  is critical. We can start to pull things together where we have

$$= \int_0^\infty \exp\{-(T_1\tilde{w}^{-\theta} + T_2)z_2^{-\theta}\} T_2\theta z_2^{-\theta-1} dz_2 \quad (45)$$

This integral has a clean solution. Use the change of variables  $u = (T_1\tilde{w}^{-\theta} + T_2)z_2^{-\theta}$ . The integral evaluates to:

$$\frac{T_2}{T_1\tilde{w}^{-\theta} + T_2} \quad (46)$$

Substituting back  $\tilde{w} = \frac{w_1 d_{11}}{w_2 d_{12}}$ :

$$\pi_{12} = \text{Prob}\{\text{country 1 buys from 2}\} = \frac{T_2(w_2 d_{12})^{-\theta}}{T_1(w_1 d_{11})^{-\theta} + T_2(w_2 d_{12})^{-\theta}} \quad (47)$$

This generalizes to  $J$  countries:

$$\pi_{nj} = \frac{T_j(w_j d_{nj})^{-\theta}}{\sum_{k=1}^J T_k(w_k d_{nk})^{-\theta}} \quad (48)$$

Recognizing the denominator as  $\Phi_n$ :

$$\pi_{nj} = \frac{T_j(w_j d_{nj})^{-\theta}}{\Phi_n} \quad (49)$$

**BOOM!** This is a key EK result: the probability that country  $j$  is the low-cost supplier to country  $n$  takes a CES-like form, with the cost competitiveness term  $T_j(w_j d_{nj})^{-\theta}$  in the numerator and

the sum of all such terms in the denominator.

## 2.6. Computing the Joint Probability of Price and Low-Cost Supplier

Now we compute the joint probability that the price takes some value and that a particular country is the low-cost supplier. Recall that we want to characterize:

$$\text{Prob} \{p_1(\omega) \leq p \mid x_{12}(\omega) = 1\} = \frac{\text{Prob} \{p_1(\omega) \leq p, p_{12}(\omega) \leq p_{11}(\omega)\}}{\text{Prob} \{p_{12}(\omega) \leq p_{11}(\omega)\}} \quad (50)$$

We already computed the denominator:  $\pi_{12} = \text{Prob}\{p_{12}(\omega) \leq p_{11}(\omega)\}$ . Now we need the numerator. The joint probability can be written as:

$$\text{Prob} \{p_1(\omega) \leq p, p_{12}(\omega) \leq p_{11}(\omega)\} = \int_0^p \left( \int_{p_{12}}^{\infty} g_{11}(p_{11}) dp_{11} \right) g_{12}(p_{12}) dp_{12} \quad (51)$$

where  $g_{nj}$  is the pdf of prices offered by source  $j$  to destination  $n$ . The logic: fix a price  $p_{12}$  from country 2, compute the probability that country 1's price  $p_{11}$  is higher (so country 2 wins), then integrate over all possible  $p_{12}$  up to  $p$ .

The inner integral is a survival function:

$$\int_{p_{12}}^{\infty} g_{11}(p_{11}) dp_{11} = 1 - G_{11}(p_{12}) \quad (52)$$

This is the probability that  $p_{11}$  exceeds  $p_{12}$ —everything above  $p_{12}$  in the distribution.

So we have:

$$\text{Prob} \{p_1(\omega) \leq p, p_{12}(\omega) \leq p_{11}(\omega)\} = \int_0^p g_{12}(p_{12}) (1 - G_{11}(p_{12})) dp_{12} \quad (53)$$

From our earlier derivation, the pdf and survival function of offered prices are:

$$g_{12}(p_{12}) = T_2(w_2 d_{12})^{-\theta} \theta p_{12}^{\theta-1} \exp \left\{ -T_2(w_2 d_{12})^{-\theta} p_{12}^{\theta} \right\} \quad (54)$$

$$1 - G_{11}(p_{12}) = \exp \left\{ -T_1 w_1^{-\theta} p_{12}^{\theta} \right\} \quad (55)$$

where in the second line we use  $d_{11} = 1$ .

Substituting:

$$\int_0^p T_2(w_2 d_{12})^{-\theta} \theta p_{12}^{\theta-1} \exp \left\{ -T_2(w_2 d_{12})^{-\theta} p_{12}^{\theta} \right\} \exp \left\{ -T_1 w_1^{-\theta} p_{12}^{\theta} \right\} dp_{12} \quad (56)$$

Combining the exponentials:

$$\int_0^p T_2(w_2 d_{12})^{-\theta} \theta p_{12}^{\theta-1} \exp \left\{ - \left( T_1 w_1^{-\theta} + T_2(w_2 d_{12})^{-\theta} \right) p_{12}^\theta \right\} dp_{12} \quad (57)$$

The sum inside the exponential is  $\Phi_1$ . Multiply and divide by  $\Phi_1$ :

$$\frac{T_2(w_2 d_{12})^{-\theta}}{\Phi_1} \int_0^p \Phi_1 \theta p_{12}^{\theta-1} \exp \left\{ -\Phi_1 p_{12}^\theta \right\} dp_{12} \quad (58)$$

The term out front is  $\pi_{12}$ . The integrand is the pdf of the price distribution  $G_1(p) = 1 - \exp\{-\Phi_1 p^\theta\}$ . So the integral equals  $G_1(p)$ :

$$\text{Prob} \{p_1(\omega) \leq p, p_{12}(\omega) \leq p_{11}(\omega)\} = \pi_{12} \cdot G_1(p) \quad (59)$$

Now we can compute the conditional probability:

$$\text{Prob} \{p_1(\omega) \leq p \mid x_{12}(\omega) = 1\} = \frac{\pi_{12} \cdot G_1(p)}{\pi_{12}} = G_1(p) \quad (60)$$

This is a crazy property that we just derived. The distribution of prices paid in country 1, conditional on country 2 being the source, is exactly the same as the unconditional distribution of prices paid. The source doesn't matter!

This is a unique property of the Fréchet distribution. It says that if we took the histogram of prices purchased from Canada (into the US) and compared it to the histogram of prices from Botswana (into the US), they would be identical. Without the Fréchet assumption, this would not hold.

## 2.7. Pulling It All Together

Recall that we wanted to compute the expenditure share from (24):

$$\frac{\int_0^1 x_{nj}(\omega) p_{nj}(\omega)^{1-\sigma} d\omega}{\int_0^1 \sum_k x_{nk}(\omega) p_{nk}(\omega)^{1-\sigma} d\omega} \quad (61)$$

Start with the denominator. This is the expected value of  $p_n(\omega)^{1-\sigma}$  where  $p_n(\omega) = \min_k p_{nk}(\omega)$  is the price actually paid. Since this is an integral over a continuum of varieties with i.i.d. draws, by the law of large numbers it equals the expectation:

$$\int_0^1 \sum_k x_{nk}(\omega) p_{nk}(\omega)^{1-\sigma} d\omega = \mathbb{E} [p_n(\omega)^{1-\sigma}] \quad (62)$$

Now the numerator. This is the integral of  $p_{nj}(\omega)^{1-\sigma}$  over varieties where  $j$  is the low-cost supplier:

$$\int_0^1 x_{nj}(\omega) p_{nj}(\omega)^{1-\sigma} d\omega = \mathbb{E} [p_n(\omega)^{1-\sigma} | x_{nj}(\omega) = 1] \cdot \text{Prob} \{x_{nj}(\omega) = 1\} \quad (63)$$

We showed that the distribution of prices paid, conditional on  $j$  being the source, is the same as the unconditional distribution. Therefore:

$$\mathbb{E} [p_n(\omega)^{1-\sigma} | x_{nj}(\omega) = 1] = \mathbb{E} [p_n(\omega)^{1-\sigma}] \quad (64)$$

And we computed  $\text{Prob}\{x_{nj}(\omega) = 1\} = \pi_{nj}$ . Putting these together:

$$\frac{\mathbb{E} [p_n(\omega)^{1-\sigma}] \cdot \pi_{nj}}{\mathbb{E} [p_n(\omega)^{1-\sigma}]} = \pi_{nj} \quad (65)$$

So the CES expenditure share equals the probability that  $j$  is the low-cost supplier:

$$\pi_{nj} = \frac{T_j(w_j d_{nj})^{-\theta}}{\Phi_n} \quad (66)$$

The fact that this worked out is crazy. It hinges critically on the property we derived earlier: the price distribution that  $j$  sells into  $n$  is the same as the overall distribution of prices that  $n$  faces. Without the Fréchet assumption, this cancellation would not occur.

### 3. Equilibrium

I won't spend tons of time on this, but here is the deal regarding closing the model. There is a condition requiring that total spending equals total income:

$$N_n w_n = \sum_{j \in J} \pi_{jn} N_j w_j. \quad (67)$$

This implies the balanced trade condition where

$$\underbrace{N_n w_n \sum_{j \neq n} \pi_{nj}}_{\text{value of imports}} = \underbrace{\sum_{j \neq n} \pi_{jn} N_j w_j}_{\text{value of exports}}. \quad (68)$$

where what is happening is that on the left hand side we are expanding out the expenditures from each source. But then we can cancel the on both sides of the equation how much  $n$  spends on their own goods and "exports" to themselves. This is then the balanced trade assumption.

As Alvarez and Lucas Jr (2007) point out, everything here is a function of the vector of wages  $\{w_1, w_2, \dots, w_J\}$ . Thus, a competitive equilibrium is characterized by a wage vector such that the optimality conditions characterize consumer demand in (9), firm pricing in (18), a sourcing strategy in (17). These conditions plus the CES and Fréchet assumption allow us to aggregate and then characterize the trade balance condition in (68).

Note that this structure is similar to what Doireann talked about in class. And Alvarez and Lucas Jr (2007) prove properties about the system defined by (68) and suggest an algorithm along the lines that Doireann described.

## 4. Welfare Gains from Trade

How welfare changes as a country opens or closes to trade has been an important point of focus in the literature and especially so following the Arkolakis et al. (2012) paper. I'm going to step back — not impose the functional forms — and then characterize how welfare changes for a change in  $d_{nj}$  in the competitive equilibrium. Then reconnect with the Arkolakis et al. (2012) paper.

Recall that the Lagrangian for the consumer problem is:

$$\mathcal{L} = \int_0^1 \sum_j x_{nj}(\omega) u(c_{nj}(\omega)) d\omega + \lambda_n \left\{ w_n N_n - \int_0^1 \sum_j x_{nj}(\omega) p_{nj}(\omega) c_{nj}(\omega) d\omega \right\}. \quad (69)$$

And the goal is to evaluate  $\frac{d\mathcal{L}}{dd_{nj}}$ . Note, I'm going to treat the  $w_n$  as the numeraire, and thus we don't need to worry about this (I'll come back to this in a bit). The total derivative with respect to  $d_{nj}$  is:

$$\frac{d\mathcal{L}}{dd_{nj}} = \underbrace{\int_0^1 \sum_k \frac{\partial \mathcal{L}}{\partial p_{nk}(\omega)} \frac{dp_{nk}(\omega)}{dd_{nj}} d\omega}_{\text{through prices}} + \underbrace{\int_0^1 \sum_k \frac{\partial \mathcal{L}}{\partial c_{nk}(\omega)} \frac{dc_{nk}(\omega)}{dd_{nj}} d\omega}_{\text{through quantities}} + \underbrace{\int_0^1 \sum_k \frac{\partial \mathcal{L}}{\partial x_{nk}(\omega)} \frac{dx_{nk}(\omega)}{dd_{nj}} d\omega}_{\text{through sourcing}}. \quad (70)$$

So this says that the gains from trade relate to (i) the direct effect from a change in trade costs **through prices** and thus I'm allowing for GE forces to feed into here and then (ii) indirect effects through how quantities change (iii) indirect effects about how sourcing patterns change. Where we are going with this is the following — all indirect effects vanish at the optimum and thus only direct effects matter.

This result may **not** be surprising. But as a history of thought and how some economists talk / talked about the new trade models it is surprising. In the EK framework specifically, people would say things like ... "well with an extensive margin on the sourcing decision, there will be

“new gains” from trade.” A sympathetic take is that one can kind of see this in the sense that if we were working with an Armington model, the sourcing effect would not be in equation (70). However, this claim is not true (at least to a first-order) and it follows from basic economic theory that the consumer is optimizing over things. And this has nothing to do with the CES and Fréchet assumption, in this sense the result I’m about to present is more general than in Arkolakis et al. (2012) paper.

Now let’s first walk through the indirect effects and argue that they are zero.

**Indirect Effect Through Quantities.** This is easy, the partial derivative of the Lagrangian with respect to  $c_{nk}(\omega)$  is:

$$\frac{\partial \mathcal{L}}{\partial c_{nk}(\omega)} = x_{nk}(\omega) [u'(c_{nk}(\omega)) - \lambda_n p_{nk}(\omega)]. \quad (71)$$

Then at the optimum, the first-order condition requires  $u'(c_{nk}(\omega)) = \lambda_n p_{nk}(\omega)$ , so:

$$\frac{\partial \mathcal{L}}{\partial c_{nk}(\omega)} = 0 \quad (72)$$

Thus the indirect effect through quantities term vanishes at the optimum.

**Indirect Effect Through Sourcing.** This is a more complicated argument because sourcing decision  $x_{nk}(\omega) \in \{0, 1\}$  is discrete, so standard calculus does not directly apply. However, we can think about two possible cases: when things inframarginal and when a small change in  $d_{nj}$  causes some varieties to switch sources.

First, for varieties where the sourcing decision is strict (one source is strictly preferred), a small change in  $d_{nj}$  does not change the discrete choice. Thus  $\frac{dx_{ik}(\omega)}{d d_{nj}} = 0$  for these varieties.

Second, what about situations where a small change induced a switch. This would have to arise from a situation where at the optimum, two sources are tied:

$$p_{nk}(\omega) = p_{nk'}(\omega) \quad (73)$$

For these varieties, the consumer is indifferent between sources. Switching from  $k$  to  $k'$  yields no change in the Lagrangian because:

$$[u(c_{nk}(\omega)) - \lambda_n p_{nk}(\omega)c_{nk}(\omega)] = [u(c_{nk'}(\omega)) - \lambda_n p_{nk'}(\omega)c_{nk'}(\omega)]. \quad (74)$$

Third, one might worry that there could be many ties that collectively matter. However, With continuous productivity distributions (as under the Fréchet assumption), ties occur on a set of

measure zero.<sup>2</sup> Therefore:

$$\int_0^1 \sum_{i,k} \frac{\partial \mathcal{L}}{\partial x_{ik}(\omega)} \frac{dx_{ik}(\omega)}{d d_{nj}} d\omega = 0. \quad (75)$$

Thus, changes in sourcing patterns have no indirect effects on welfare. This is the important indirect effect to rule out because it rules out that there are **no extra gains** from having an active extensive margin for where to source a good.

**Direct Effects Through Prices.** What I've argued is that the only source of gains from trade are direct effects. What remains is only the effect through prices:

$$\frac{d\mathcal{L}}{d d_{nj}} = \int_0^1 \sum_k \frac{\partial \mathcal{L}}{\partial p_{nk}(\omega)} \frac{dp_{nk}(\omega)}{d d_{nj}} d\omega. \quad (76)$$

Then partial derivative of the Lagrangian with respect to prices is:

$$\frac{\partial \mathcal{L}}{\partial p_{nk}(\omega)} = -\lambda_n x_{nk}(\omega) c_{nk}(\omega) \quad (77)$$

and thus

$$\frac{d\mathcal{L}}{d d_{nj}} = -\lambda_n \int_0^1 \sum_k x_{nk}(\omega) c_{nk}(\omega) \frac{dp_{nk}(\omega)}{d d_{nj}} d\omega. \quad (78)$$

Now consider how prices change. The price is  $p_{nk}(\omega) = \frac{w_k d_{nk}}{z_k(\omega)}$ , so:

$$\frac{d \ln p_{nk}(\omega)}{d \ln d_{nj}} = \begin{cases} 1 + \frac{d \ln w_j}{d \ln d_{nj}} & \text{if } k = j \\ \frac{d \ln w_k}{d \ln d_{nj}} & \text{if } k \neq j \end{cases} \quad (79)$$

What we have then is

$$\frac{d\mathcal{L}}{d d_{nj}} = \frac{-\lambda_n}{d_{nj}} \left[ X_{nj} \left( 1 + \frac{d \ln w_j}{d \ln d_{nj}} \right) + \sum_{k \neq j} X_{nk} \frac{d \ln w_k}{d \ln d_{nj}} \right] \quad (80)$$

where  $X_{nj} = \int_0^1 x_{nj}(\omega) p_{nj}(\omega) c_{nj}(\omega) d\omega$  is total expenditure on goods from  $j$  and I inserted the elasticities (which was what allowed me to pull out a  $p_{nj}(\omega)$  and construct expenditure).

This is nice, but there are a couple of issues to clear up to get things into the proper units. First, this is the change in utility which is not a meaningful number. But we can convert it to

---

<sup>2</sup>There is a third issue that some switches are occurring. However, these are precisely varieties that were near-indifferent. Hence the welfare effect from the discrete reallocation across sources is second order: the mass of switchers is  $\mathcal{O}(\Delta)$  and the surplus that they could yield is  $\mathcal{O}(\Delta)$  therefore the total affect of these forces are second-order  $\mathcal{O}(\Delta^2)$ .

the “dollars” or what ever numeraire we have by dividing through by the marginal utility of wealth. Just as a recap to understand units here,  $\lambda_n$  converts dollars into utils, i.e. how many utils do I get per dollar. Then  $1/\lambda_n$  converts utils into dollars.

Now one more observation, define  $U_n$  as utility for the consumer in  $n$  at the current equilibrium. Then  $W_n \equiv \frac{1}{\lambda_n} U_n$  has the interpretation as the total number of dollars that are required to deliver  $U_n$ . We also know that the number of dollars to do so is given by  $E_n$  which is total expenditure, thus  $W_n = E_n$ . So divide both sides by the ratio of trade costs to expenditure gives

$$\frac{d \ln W_n}{d \ln d_{nj}} = -\pi_{nj} \left( 1 + \frac{d \ln w_j}{d \ln d_{nj}} \right) - \sum_{k \neq j} \pi_{nk} \frac{d \ln w_k}{d \ln d_{nj}} \quad (81)$$

and this can be rewritten as:

$$\frac{d \ln W_n}{d \ln d_{nj}} = -\pi_{nj} - \sum_k \pi_{nk} \frac{d \ln w_k}{d \ln d_{nj}} \quad (82)$$

The welfare effect has two components. First there is the effect  $\pi_{nj}$  which is the share spent on goods from  $j$  times the direct price reduction from lower trade costs. This is the (partial equilibrium) envelope result: a 1% decrease in  $d_{nj}$  increases real income by  $\pi_{nj}$  percent. The welfare cost of lower trade costs is proportional to the expenditure share on the affected trade route.

This result on the first effect, turns out to have a super tight connection to standard consumer theory regarding the measurement of the welfare effects of change in prices. Deaton (1989) is a key reference with the insight that initial expenditure shares are the sufficient statistics needed to compute the welfare effects of price changes (in this case induced by a reduction in trade costs) to a first order.

Now there is a second GE effect  $\sum_k \pi_{nk} \frac{d \ln w_k}{d \ln d_{nj}}$ : a share-weighted sum of how all source prices change through wage adjustments. This is a “leakage” term where that word is sometimes used in public finance. Here leakage is represented by how other countries wages adjust given the shock. Or put another way, how the terms of trade adjust given the shock. Note if this country were small, then this term would be small.

One can show that the GE effects in **aggregate** net out to zero. In the appendix A, I show this. So if we look at welfare of other countries and then sum up these GE effects, globally they are zero and the only “true” gains from  $d_{nj}$  are given by the share  $\pi_{nj}$ . Viewed in this light, these GE effects are simply redistributing the gains from trade across countries, and thus country  $n$  does not recipe the full benefit of the reduction in  $d_{nj}$ .

Finally notice that CES or Fréchet did not play a role in this argument. This is very general by

arguing that only direct effects matter and those are characterized by expenditures and in GE how wages in other destinations respond.

#### 4.1. Hang On. What about Arkolakis et al. (2012)?

At this point you should be totally confused. Arkolakis et al. (2012) told us one thing — only two sufficient statistics matter for the gains from trade. And I've said something else. How can they both be true. They are and let me show you how.

First, I'm going to derive a similar formula to (82) but using ACRs formula. So we know that real income is

$$W_n \propto \pi_{nn}^{\frac{-1}{\theta}} \quad (83)$$

and then the percentage change in real income with respect to a change in trade costs is

$$\frac{d \ln W_n}{d \ln d_{nj}} = \frac{-1}{\theta} \times \frac{d \ln \pi_{nn}}{d \ln d_{nj}} \quad (84)$$

This should look normal so far.

Now, here is my argument which has a similar flavor to ACR. Rather than working through assumptions about the distribution on productivity or demand, I will just **assert** that aggregate trade shares take a "CES-like" form. We've already shown that this is the case for EK, but for now, let's just assume we did not see that.

**Assumption: Expenditure Shares Take a CES form.** Mathematically, this assertion is

$$\pi_{nj} = \frac{(w_j d_{nj})^{-\theta}}{\sum_{j' \in J} (w_{j'} d_{nj'})^{-\theta}} \quad (85)$$

Now lets compute the elasticity of  $\frac{d \ln \pi_{nn}}{d \ln d_{nj}}$  under this assumption. Recall with the normalization that  $w_n = 1$  we have

$$\frac{d \ln \pi_{nn}}{d d_{nj}} = -\frac{d \ln \Phi_n}{d d_{nj}} \quad (86)$$

Then expand out  $\Phi_n$  and take the total derivative

$$\frac{d \ln \Phi_n}{d d_{nj}} = \frac{1}{\Phi_n} \left[ \frac{-\theta(w_j d_{nj})^{-\theta}}{d_{nj}} + \sum_k \frac{-\theta(w_k d_{nk})^{-\theta}}{w_k} \frac{dw_k}{d d_{nj}} \right] \quad (87)$$

then put in elasticity form by dividing through appropriately and noting that we have shares

when the  $\Phi_{in}$  is multiplied through giving

$$\frac{d \ln \Phi_n}{d \ln d_{nj}} = -\theta \pi_{nj} - \theta \sum_k \pi_{nk} \frac{d \ln w_k}{d \ln d_{nj}} \quad (88)$$

Then insert this into (86) and in turn (84)

$$\begin{aligned} \frac{d \ln W_n}{d \ln d_{nj}} &= \frac{-1}{\theta} \times \left[ -\theta \pi_{nj} - \theta \sum_k \pi_{nk} \frac{d \ln w_k}{d \ln d_{nj}} \right] \\ &= -\pi_{nj} - \sum_k \pi_{nk} \frac{d \ln w_k}{d \ln d_{nj}} \end{aligned} \quad (89)$$

And we are back to my Deaton / Hulton -like result in (82). What is going on here? Here is my take

- Equation (82) is very general and says that only direct effects matter and those are characterized by the share of expenditure on the source plus share weighted GE effects. And the argument makes clear **why** a new margin like switching sources would not matter for the gains from trade (to a first order). CES or Fréchet did not play a role in this argument.
- A CES-like expenditure demand system (however that is deliver) provides a very tight connection between the share of expenditure on the source and the product of the trade elasticity and the home expenditure share *change*. This is the result (89). In the EK specific context, CES and Fréchet deliver a CES-like expenditure demand system and this is akin to the notion that these assumptions in the EK model satisfy their Macro restrictions.
- Notice, that both my equation and ACR handle GE effects. However, one can see how the ACR and the demand system that they impose dramatically simplifies things when GE is considered — all of that stuff is baked into the home trade share. What this also means, per my discussion about the GE effects, is that the ACR gains **are not** a pure efficiency gains but also represent redistribution through the terms of trade from one country to another.
- An important point is local versus global. The ACR result is a global result, not first order. Whereas equation (82) is local. This is an under-appreciated part of their result is the globally, different models are the same (near autarky, away etc.), and this is where the functional form assumptions deliver stronger results.

## A. GE wage effects are redistribution

I'm now going to make the argument that in general equilibrium, the wage effects are pure redistribution across countries. What one country loses through leakage, the other gains.

I'm going to simplify things so we have two countries. Normalize  $w_1 = 1$  as the numeraire. Trade balance requires:

$$N_1\pi_{12} = N_2\pi_{21}w_2. \quad (90)$$

From our earlier derivation, the welfare effects of a change in  $d_{12}$  in **country 1** are

$$\frac{d \ln W_1}{d \ln d_{12}} = -\pi_{12} - \pi_{12} \frac{d \ln w_2}{d \ln d_{12}}. \quad (91)$$

We can do the same thing for **country 2**

$$\frac{d \ln W_2}{d \ln d_{12}} = \pi_{21} \frac{d \ln w_2}{d \ln d_{12}}. \quad (92)$$

Country 2 has receives no direct effect (the trade cost  $d_{12}$  is the cost of shipping to country 1). Its welfare changes only through the GE wage adjustment.

A key thing to resolve is that the formulas are in elasticity form. The leakage argument is in levels, so we need to say the level gain from one place nets off from a level loss from another.

So country 1's welfare in levels:

$$\frac{dW_1}{d \ln d_{12}} = W_1 \frac{d \ln W_1}{d \ln d_{12}} = -N_1\pi_{12} - N_1\pi_{12} \frac{d \ln w_2}{d \ln d_{12}} \quad (93)$$

where the last term is leakage in levels. Then country 2's welfare in levels:

$$\frac{dW_2}{d \ln d_{12}} = W_2 \frac{d \ln W_2}{d \ln d_{12}} = N_2\pi_{21}w_2 \frac{d \ln w_2}{d \ln d_{12}} \quad (94)$$

which is all leakage.

**Here is the important observation.** Use the trade balance condition  $N_1\pi_{12} = N_2\pi_{21}w_2$  to rewrite country 2's gain

$$\begin{aligned} \frac{dW_2}{d \ln d_{12}} &= \underbrace{N_1\pi_{12} \frac{d \ln w_2}{d \ln d_{12}}}_{=\text{-leakage from 1}} \\ &= \text{-leakage from 1} \end{aligned} \quad (95)$$

These are exactly equal and opposite. What country 1 loses through the GE wage adjustment,

country 2 gains. The direct effect  $-\pi_{12}$  is the real resource saving from lower trade costs. The GE wage effects merely redistribute between the two countries, summing to zero.
